

# Econometrics for Financial Markets

Slanzi Marco

October 24, 2025

## **1 Report on the analysis**

## 1.1 Univariate Volatility Analysis

The analysis of the financial asset expressed in logarithmic form ("lp") reveals time-varying volatility patterns, that are common in financial markets.

The analysis begins with the unconditional statistical properties<sup>1</sup>, where we observe the typical features of financial log-returns: a mean near zero (0.006891) with high variability (standard deviation of 0.222634), reflecting the stochasticity of asset price movements<sup>1</sup>.

Stationarity is confirmed by the Augmented Dickey-Fuller test (statistic = -81.24, p-value = 0), validating the application of GARCH methodology.

The Jarque-Bera test strongly rejects normality (statistic = 2973.72, p-value = 0), revealing fat tails that in the returns distribution<sup>2</sup>.

This non-normal behavior is aligned with the extreme market movements occurring in financial markets.

The Engle's ARCH test provides evidence of volatility clustering (conditional heteroscedasticity), statistic = 292.764, p-value =  $1.55 \times 10^{-55}$ , indicating that large price movements tend to be followed by large movements in both direction<sup>3</sup>.

The analysis also used a non parametric volatility tool, the Exponentially Weighted Moving Average (EWMA)<sup>4</sup>.

Further the research reveals that the GJR-GARCH(1,1) specification with Student's t-distribution to model the residuals distribution provides the best characterization of volatility dynamics (Akaike Information Criterion = 58742.89).

The GJR-GARCH(1,1) allows to capture asymmetric effects of positive and negative shocks on volatility through the  $\gamma$  parameter.

The parameters estimated with the Maximum Likelihood Estimation (MLE) offer an interpretation of the asset behavior: the sum of the parameters ( $\alpha + \beta + 1/2 * \gamma \approx 0.9095$ ) which is less than 1 ensures the stationarity of the model.

The parameter  $\alpha$  represents the immediate reaction to shocks on the market and is equal to 0.1103;  $\beta$  represents how much of the past volatility lasts in current volatility, and it is equal to 0.8162, showing high persistence.<sup>5</sup>

The negative leverage effect ( $\gamma = -0.034$ , p-value less than 0.05) captures the asymmetric response of volatility to positive versus negative returns.

Since  $\gamma$  is negative, positive shocks tend to increase next-period volatility more than a negative return of equal size, which is quite unusual for the stock market, while this behavior has been observed for certain other asset classes such as safe-haven assets like gold ([https://www.researchgate.net/publication/396033458\\_The\\_Asymmetric\\_Effect\\_of\\_Market\\_Uncertainty\\_on\\_Safe\\_havens\\_Inverted\\_Asymmetry\\_and\\_Contagion\\_During\\_COVID-19\\_Periods](https://www.researchgate.net/publication/396033458_The_Asymmetric_Effect_of_Market_Uncertainty_on_Safe_havens_Inverted_Asymmetry_and_Contagion_During_COVID-19_Periods)).

This asymmetry is shown in the impulse response functions<sup>6</sup>.

For risk management purposes the VaR and ES were computed in two different methods: the parametric and the empirical<sup>7</sup>.

The parametric 1-day Value-at-Risk of -0.303440 at the 10% level and Expected Shortfall of -0.449485 provide quantitative measures for capital allocation and risk limits<sup>8</sup>.

The Generalized Normal distribution emerges as optimal for modeling standardized residuals (AIC = 18462.54, KS p-value = 0.361)<sup>9</sup>, while the Generalized Extreme Value distribution models accurately the left tail (AIC: 628.47 vs alternatives 6728), offering capability for capturing extreme loss scenarios<sup>10</sup>.

The empirical 1-day Value-at-Risk is -0.296903 at the 10% level and Expected Shortfall of -0.3839.

## 1.2 Multivariate Volatility Analysis: Interconnected Market Dynamics

The multivariate analysis examines the interconnected volatility paths of three financial assets<sup>11</sup> between the 2012 and 2021 revealing interdependence patterns and time-varying correlation, which tends to converge in periods of market high volatility and diminish during lower volatility regime. The methodological approach begins with univariate modeling<sup>12</sup> of the time-series, revealing that the assets require distinct specifications<sup>13</sup>: EGARCH for Prices 1 and 2, GJR-GARCH for Price 3. <sup>141516</sup>.

Price1 represents a case where EGARCH provides efficient asymmetric volatility capture with optimal model fit (AIC: 10174.3). Price2 exhibits extreme characteristics that demand EGARCH exponential formulation to manage fat-tailed behavior (kurtosis = 14.94, JB p = 0) with strong positive skewness (0.716908). Price3 demonstrates classic financial asset behavior where GJR-GARCH's explicit leverage parameter  $\gamma$  captures the volatility asymmetry.

The parameters for each model were estimated using the Quasi-Maximum Likelihood(QML) method.

The universal selection of Student's t-distribution among all models confirms the necessity of heavy-tailed error distributions to explain the significant excess kurtosis present in all three return series, with all models successfully eliminating residual ARCH effects in squared returns.

All three models demonstrate good volatility capture but the Ljung-Box test on residuals( 0.00) shows significant autocorrelation in the standardized errors, meaning the GARCH models removed volatility clustering but left unsolved predictable patterns in the return series ; this led to the improvement of the models.

The autocorrelation issue is addressed through the adoption of the ARMA-GARCH models, in particular AR1-EGARCH11-t for Price1 and Price2, AR1-GJR11-t for Price3.

With the ARMA implementation, the mean equations was added: the ARMA structure successfully captured the dependency of past returns on its own values, not captured by GARCH.

The residual analysis of this new model showed the elimination of the autocorrelation for Price1 :LB p: 0.00  $\rightarrow$  0.494, improvement for Price2 LB p:0.047  $\rightarrow$  0.088, while Price3 still exhibits slight autocorrelation (LB p = 0.011).

The CCC(Constant Conditional Correlation) matrix shows positive correlations: Price1-Price3 (0.374) strongest, Price1-Price2 (0.319) moderate, and Price2-Price3 (0.257).

All correlations are statistically significant but constrained to be constant over time, ignoring the dynamic nature of financial market interdependencies and the volatility clusters for correlation, hence the DCC(Dynamic Conditional Correlation) model is implemented.

The DCC parameter estimates<sup>17</sup> reveal the stationarity in correlation dynamics ( $\zeta + \xi = 0.996282$ ) less than 1 and the high persistence of the correlation structures confirms long memory, with dislocations taking long time to normalize, with a half-life of 186 periods.

The minimal responsiveness of correlation to new shocks ( $\zeta = 0.007145$ ) represents the slow adjustments of the market to the link between the assets.

The statistical superiority of DCC over Constant Conditional Correlation is clear and economically significant<sup>18</sup>. The likelihood ratio test statistic of 40.0214 (p-value = 0.00) provides evidence against the constant correlation hypothesis. While the average DCC correlations approximates in its average their CCC counterparts, the distinction is in DCC's capacity to capture time-varying interdependence.

This finding carries implications for portfolio management: constant correlation assumptions are statistically inadequate and economically misleading.

The dynamic correlation patterns<sup>19</sup> reveal meaningful economic relationships that evolve over time<sup>20</sup>. These time-varying interconnections reflect the change in the perceptions of risk factors and evolving economic linkages between the assets<sup>21</sup>.

This finding underscores that diversification benefits are time-varying rather than static, requiring continuous monitoring as correlation structures evolve with changing market perceptions of

common risk factors.

### 1.3 Vector Autoregression Analysis of Oil Price-Growth Rate-Inflation

The VAR analysis provides evidence of dynamic interrelationships among oil prices, inflation, and GDP growth<sup>22</sup>, which allows an understanding of how macro-economical data and the energy sector are linked in small open economies.

The results prove statistically significant and economically meaningful relationships, offering insights for macroeconomic policy<sup>23</sup>.

Stationarity testing<sup>24</sup>, confirming that all three variables exhibit strong stationarity properties (ADF p-values = 0.000), enabling to use VAR modeling without transformation.

The optimal lag length selection process demonstrates support for lag 1, with AIC and BIC criteria.

The Johansen test reveals three cointegrating relationships at 95 percent confidence level<sup>25</sup>, indicating strong long-run equilibrium among the variables.

The analysis goes into a well-defined from literature transmission channel: Oil Price Shocks → Inflation → GDP Growth.

Granger causality tests<sup>26</sup> reveals bidirectional relationships: inflation significantly causes oil prices increase ( $p = 0.0001$ ), oil prices cause GDP growth ( $p = 0.0160$ ), and inflation causes GDP growth ( $p = 0.0006$ ).

This causal structure reflects the macroeconomic reality, where energy costs influence production costs and consequently affect overall price levels and economic activity<sup>27</sup>.

VAR coefficient estimates<sup>28</sup> quantify these relationships showing high persistence between all variables: (0.46) for oil prices, (0.551) for inflation, (0.521) for GDP growth).

More importantly, the cross-variable impacts show economic significance: oil prices have a 0.327 impact on inflation, proving the direct cost effect of energy prices, while past GDP growth positively affects current GDP growth (0.521), showing strong persistence in economic growth patterns, capturing the growth-inhibiting effects of price instability.

The economic magnitude of these relationships is relevant: a one standard deviation oil price shock (0.573) generates a (0.187) inflation impact, representing 31% of inflation's standard deviation.

The dynamic analysis through impulse response functions<sup>29</sup> reveals persistent shock propagation with oil price effects having peaks at 6-8 months and lasting more than 24 months.

Oil price shocks have long term effects on the macro-economy, requiring policy structural responses rather than temporary interventions.

Forecast error variance decomposition<sup>30</sup> exhibits cross-variable influences, with oil shocks that explain 30-40% of inflation variance and inflation shock that impact in an increasing pattern the GDP growth at longer periods, highlighting the secondary transmission mechanisms that takes place.

The model shows strong out-of-sample forecasting performance<sup>31</sup> with RMSE values of (0.2972) for oil prices and (0.2734) for inflation, supporting policy applications<sup>32</sup>.

The higher GDP growth forecast error (0.7544) reflects the difficulty on growth rate predictions but still is within acceptable bounds for the analysis.

Model validation<sup>33</sup> confirms robust statistical properties across all diagnostic dimensions<sup>34</sup>.

The Ljung-Box tests (p-values  $> 0.72$ ) confirm the lack of autocorrelation, while ARCH effects testing (p-values  $> 0.47$ ) validates the constant variance assumption.

The detection of 3 cointegrating relationships suggests that the VAR model can have only short-term investigation and forecasting relevance, limiting the understanding of long-term relations between variables.

From a policy perspective, the findings lead to crucial implications:

Monetary authorities should monitor oil prices given the strong (0.327) impact coefficient and significant Granger causality.

The quantification shows that a 10% oil price increase generates (0.033) inflation increase, which is quite consistent.

Oil price stabilization contributes to macroeconomic stability through inflation and growth relation. The choice to proceed with VAR in levels despite cointegration is for a practical balance between theoretical rigor and forecasting utility: the VAR specification offers interpretation of short-run dynamics and impulse responses.

The diagnostic testing provides confidence in the model's statistical adequacy, with validation checks returning positive results; stationarity confirmed, no autocorrelation, no ARCH effects, but high cointegration.

The economic interpretation of cointegrated relationships suggests long run interdependence between variables, where no variable can permanently deviate from the others without eventual correction.

This deep equilibrium shows the interdependences of energy markets, price stability, and economic growth in modern economies. The high persistence parameters suggest that shocks have lasting effects and policy interventions may require sustained implementation and time to achieve desired outcomes.

In conclusion, the comprehensive analysis demonstrates that oil price shocks represent significant macroeconomic role with measurable impacts on inflation and growth, supporting its key role which requires constant monitoring in economic policy formulation and forecasting.

# A Methodological Foundations and Statistical Analysis

## A.1 Analysis 1: Univariate Volatility Modeling

### A.1.1 Theoretical Framework

The analysis employs GARCH-family models following Bollerslev (1986) and Engle (1982). The base GARCH(1,1) specification:

$$\begin{aligned}r_t &= \mu + \varepsilon_t \\ \varepsilon_t &= \sigma_t z_t \\ \sigma_t^2 &= \omega + \alpha \varepsilon_{t-1}^2 + \beta \sigma_{t-1}^2\end{aligned}$$

Asymmetric extensions include GJR-GARCH for leverage effects:

$$\sigma_t^2 = \omega + \alpha \varepsilon_{t-1}^2 + \gamma I_{t-1} \varepsilon_{t-1}^2 + \beta \sigma_{t-1}^2$$

where  $I_{t-1} = 1$  if  $\varepsilon_{t-1} < 0$ , and 0 otherwise.

### A.1.2 Methodological Procedure

1. **Data Preparation:** Logarithmic returns computation with percentage scaling
2. **Tests:**
  - Stationarity testing (ADF test)
  - Normality test (Jarque-Bera test)
  - ARCH effects detection (Engle's test)
3. **Model Estimation:**
  - GARCH, EGARCH, GJR-GARCH, APARCH.
  - Student's t-distribution for residuals
  - Maximum likelihood estimation
4. **Model Selection:** Akaike Information Criterion (AIC) comparison.
5. **Diagnostic Testing:**
  - Standardized residual analysis
  - Ljung-Box tests for autocorrelation
  - ARCH-LM tests for remaining volatility clustering
6. **Risk Measurement:**
  - Parametric VaR/ES using fitted distributions
  - Empirical VaR/ES from historical quantiles
  - Conditional volatility scaling
7. **Additional Analyses:**
  - Impulse response functions
  - Multi-period volatility forecasting
  - Tail distribution fitting

## A.2 Analysis 2: Multivariate CCC-DCC GARCH Modeling

### A.2.1 Theoretical Framework

**Constant Conditional Correlation (CCC) Model** The CCC model (Bollerslev, 1990) provides a multivariate volatility framework with time-varying volatilities but constant correlations matrix:

$$\begin{aligned}r_t &= \mu_t + \varepsilon_t \\ \varepsilon_t &= H_t^{1/2} z_t \\ H_t &= D_t R D_t \\ D_t &= \text{diag}(\sigma_{1,t}, \sigma_{2,t}, \dots, \sigma_{N,t})\end{aligned}$$

#### Components:

- $D_t = \text{diag}(\sigma_{1,t}, \sigma_{2,t}, \dots, \sigma_{N,t})$ : Univariate GARCH volatilities of each asset
- $R$ : Unconditional correlation matrix between the assets
- $\sigma_{i,t}$ : Conditional volatility for asset  $i$  at time  $t$
- $z_t$ : Standardized residuals vector  $\sim i.i.d.(0, I)$

#### CCC Estimation:

1. Estimation of univariate GARCH models for each asset to obtain  $D_t$
2. Find constant correlation matrix  $R$  from the standardized residuals
3. Construct conditional covariance matrix  $H_t = D_t R D_t$

**Dynamic Conditional Correlation (DCC) Model** The DCC model (Engle, 2002) improves the CCC model by considering time-varying correlations between the variables:

$$\begin{aligned}H_t &= D_t R_t D_t \\ Q_t &= (1 - \zeta - \xi) \bar{R} + \zeta(\varepsilon_{t-1} \varepsilon'_{t-1}) + \xi Q_{t-1} \\ R_t &= \text{diag}(Q_t)^{-1/2} Q_t \text{diag}(Q_t)^{-1/2}\end{aligned}$$

#### Key Components:

- $D_t = \text{diag}(\sigma_{1,t}, \sigma_{2,t}, \dots, \sigma_{N,t})$ : Univariate GARCH volatilities
- $R_t$ : Time-dependent correlation matrix
- $\bar{R}$ : Unconditional correlation matrix
- $Q_t$ : dynamic correlation matrix, from which is built  $R_t$
- $\zeta$ : Responsiveness of correlation to new shocks
- $\xi$ : Persistence parameter (memory of past correlations)
- Constraints:  $\zeta > 0$ ,  $\xi > 0$ ,  $\zeta + \xi < 1$

#### Two-Stage Estimation:

1. Estimate univariate GARCH models for each asset to obtain  $D_t$ , univariate volatilities
2. Estimate DCC parameters ( $\zeta, \xi$ ) using standardized residuals through Maximum/Quasimaximum Likelihood Estimation techniques

## A.2.2 Methodological Procedure

### 1. Data Preparation and Preliminary Analysis:

- Loading the price series from Excel Sheet 2
- Computation of log-returns with percentage scaling ( $\times 100$ ) for numerical stability
- Cointegration testing using Johansen test to assess long-run relationships

### 2. Preliminary Tests:

- Stationarity testing (ADF test) on return series
- Normality test (Jarque-Bera test)
- ARCH effects detection (Engle's ARCH-LM test)

### 3. Univariate GARCH Modelling:

- Candidate specifications: GARCH(1,1)-t, GJR-GARCH(1,1)-t, EGARCH(1,1)-t
- Maximum likelihood estimation with Student's t-distribution for residuals
- Model selection via Akaike Information Criterion (AIC)
- Diagnostic testing on standardized residuals

### 4. ARMA-GARCH Implementation:

- AR(1) mean specification implemented to eliminate/reduce residual autocorrelation
- Choice based on Ljung-Box test results showing significant autocorrelation
- Specifications: AR(1)-GARCH(1,1)-t, AR(1)-GJR-GARCH(1,1)-t, AR(1)-EGARCH(1,1)-t
- Final model selection based on AIC improvement over non-ARMA specifications

### 5. Constant Conditional Correlation (CCC) Estimation:

- Computation of constant correlation matrix from aligned standardized residuals
- Benchmark model for DCC comparison

### 6. Standardized Residuals Preparation for DCC:

- Extraction of standardized residuals from selected ARMA-GARCH models
- Ljung-Box and AIC test to confirm the reduction of autocorrelation

### 7. DCC Model Estimation:

- Computation of unconditional correlation matrix  $\bar{R} = \frac{1}{T} \sum \varepsilon_t \varepsilon_t'$
- DCC log-likelihood optimization with constraints:  $\zeta > 0$ ,  $\xi > 0$ ,  $\zeta + \xi < 1$
- Multiple optimization attempts with QuasiMaximum Likelihood
- Numerical regularization ( $\epsilon_{reg} = 1 \times 10^{-8}$ ) for positive definiteness

### 8. Dynamic Correlation Computation:

- Time-varying correlation matrices:  $R_t = \text{diag}(Q_t)^{-1/2} Q_t \text{diag}(Q_t)^{-1/2}$
- Positive definiteness verification at each time period
- Computation of average DCC correlation matrix

## 9. Model Comparison:

- Likelihood ratio tests between CCC and DCC specifications
- Information criteria comparison: Akaike (AIC) and Bayesian (BIC)
- Testing of DCC improvement

## 10. Validation:

- Standardized residual analysis for each ARMA-GARCH model
- Ljung-Box tests for autocorrelation in levels and squares
- ARCH-LM tests for remaining conditional heteroscedasticity
- Jarque-Bera tests

## A.3 Analysis 3: Vector Autoregression Framework and Estimation Methodology

### A.3.1 Theoretical Framework

The Vector Autoregression (VAR) methodology, Sims (1980), provides a flexible multivariate framework to capture dynamic interrelationships among multiple time series without imposing strong restrictions.

The general VAR(p) model specification for our three-variable system:

$$\begin{bmatrix} \text{oil\_price}_t \\ \text{inflation}_t \\ \text{gdp\_growth}_t \end{bmatrix} = c + \sum_{i=1}^p A_i \begin{bmatrix} \text{oil\_price}_{t-i} \\ \text{inflation}_{t-i} \\ \text{gdp\_growth}_{t-i} \end{bmatrix} + \begin{bmatrix} \varepsilon_{1t} \\ \varepsilon_{2t} \\ \varepsilon_{3t} \end{bmatrix}$$

where  $c$  is a  $3 \times 1$  vector of constants,  $A_i$  are  $3 \times 3$  coefficient matrices, and  $\varepsilon_t \sim N(0, \Sigma)$  is the vector of shocks with covariance matrix  $\Sigma$ .

### A.3.2 Methodological Procedure

#### 1. Data Preparation and Quality Control:

- Loading monthly data from Excel Sheet 3
- Variable standardization
- Temporal alignment and missing value analysis
- Monthly frequency conversion of data

#### 2. Data Analysis:

- Time series visualization of all three variables
- Correlation matrix
- Descriptive statistics of the time series

#### 3. Granger Causality Test:

- Bivariate VAR tests across lags 1-8 to test cointegration pairwise
- Minimum p-value approach to identify Granger causality
- F-test statistic calculation with significance validation (How much adding a lagged variable improves the predictability of another variable)

- Causality matrix construction to visualize the results

#### 4. **Stationarity Test and Data Transformation:**

- Augmented Dickey-Fuller test(ADF  $p < 0.05$ )
- KPSS test(KPSS  $p < 0.05$ )
- Data-driven differencing decision based on joint significance

#### 5. **Lag Order Selection:**

- Multi-criteria comparison: Akaike (AIC), Bayesian (BIC)
- Maximum lag search up to 12 periods
- Final lag selection based on the previous criteria(Lag=1)

#### 6. **VAR Model Estimation:**

- Maximum likelihood estimation with OrdinaryLeastSquares
- Train-test split (12-month of the sample for validation)
- Coefficient significance testing p values from the standard errors
- AIC and BIC criteria to choose the more appropriate lag and model specification

#### 7. **Residual Diagnostics:**

- Durbin-Watson test for autocorrelation
- Ljung-Box test for residual correlation
- ARCH Engle's test for conditional heteroscedasticity
- Residual distribution and correlation analysis

#### 8. **Cointegration Analysis:**

- Johansen trace test found strong cointegration(COMPLETE SYSTEM INTERDEPENDENCE)
- Maximum eigenvalue test for cointegration rank determination, evidence against the no cointegration hypothesis
- Critical value comparison at 95% confidence level

#### 9. **Forecast Evaluation:**

- 12-month forecasting
- Root Mean Squared Error (RMSE) for forecast accuracy understanding
- Forecast performance comparison between variables using RMSE

#### 10. **Plots and interpretation:**

- Impulse Response Functions
- Forecast Error Variance Decomposition, to understand interdependencies of variiances
- Structural break analysis, economic relationship stable in different regimes
- Rolling correlation and volatility analysis, to capture time-varying volatility patterns

#### 11. **Model Validation:**

- Diagnostic check
- Out-of-sample performance assessment
- Economic consistency confirmed

## B Tables and Graphs

Table 10: Standardized Residuals Diagnostics with Autocorrelation Assessment

Series	Model	Mean	Std	LB10 p	Autocorrelation
logret_Price1	AR1-EGARCH11-t	0.005377	1.010679	0.493829	Removed
logret_Price2	AR1-EGARCH11-t	0.019708	1.031549	0.087625	Mostly Removed
logret_Price3	AR1-GJR11-t	0.000942	1.011410	0.010617	Improved

Note: LB10 p = Ljung-Box test p-value at lag 10. Autocorrelation assessment:  $p > 0.10$  = Removed,  $0.05 \leq p \leq 0.10$  = Mostly Removed,  $p < 0.05$  = Improved.

Table 11: Dramatic Autocorrelation Reduction with ARMA-GARCH

Series	Model	LB10 without ARMA	LB10 with ARMA
logret_Price1	AR1-EGARCH11-t	0.000000	0.493829
logret_Price2	AR1-EGARCH11-t	0.046663	0.087625
logret_Price3	AR1-GJR11-t	0.000000	0.010617

Table 12: Optimal Univariate Model Selection for Multivariate Analysis

Asset	Selected Model	AIC
Price1	AR(1)-EGARCH(1,1)-t	10015.40
Price2	AR(1)-EGARCH(1,1)-t	11225.34
Price3	AR(1)-GJR-GARCH(1,1)-t	9582.43

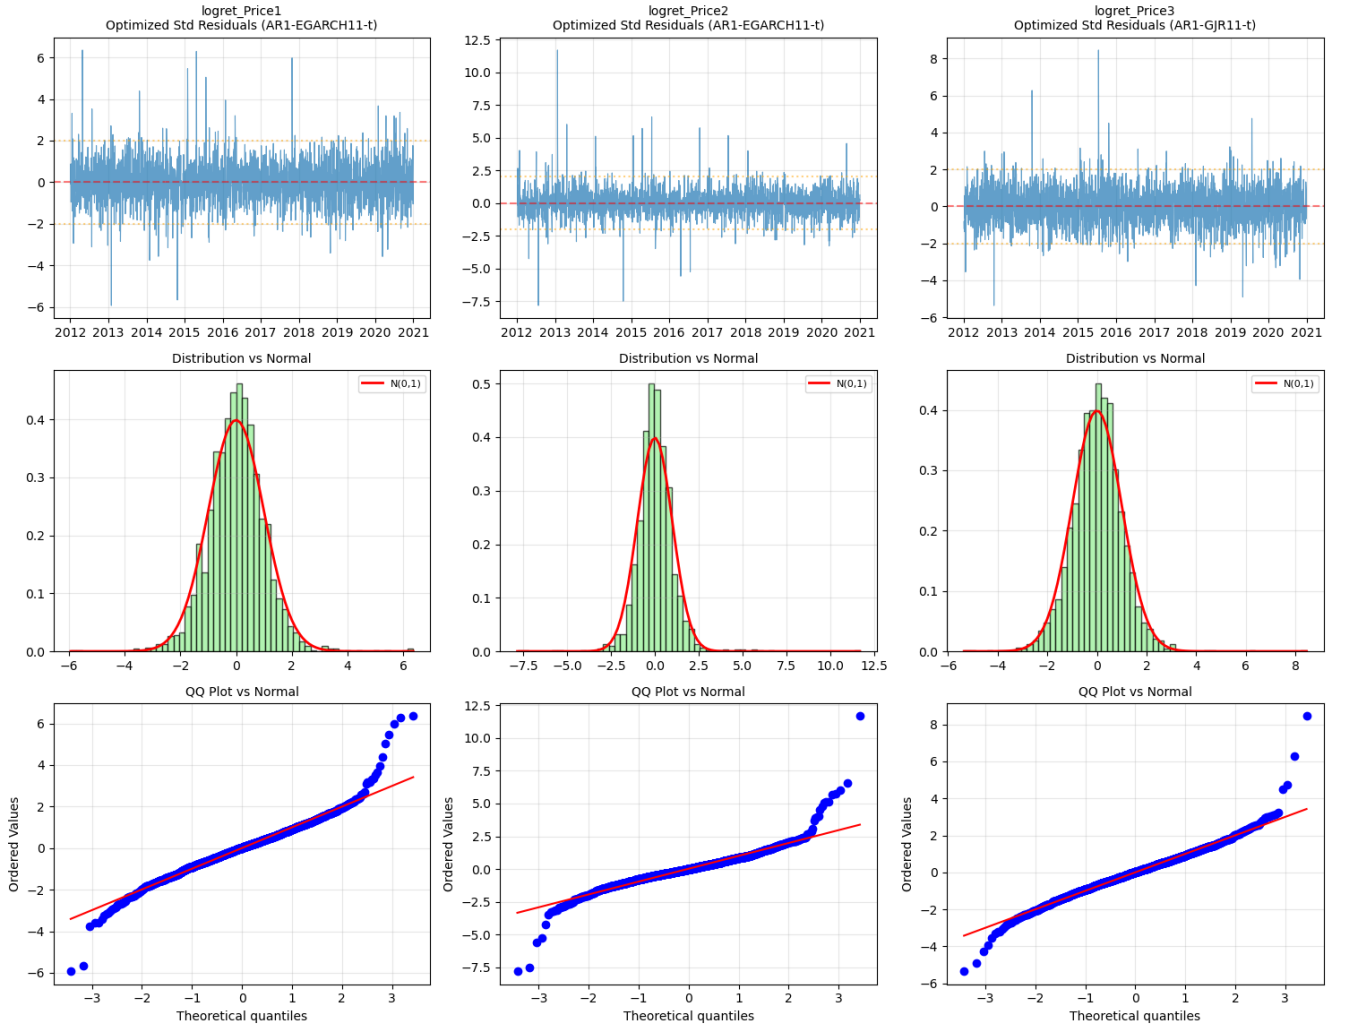

Figure 21: Optimized ARMA-GARCH Standardized Residuals Analysis

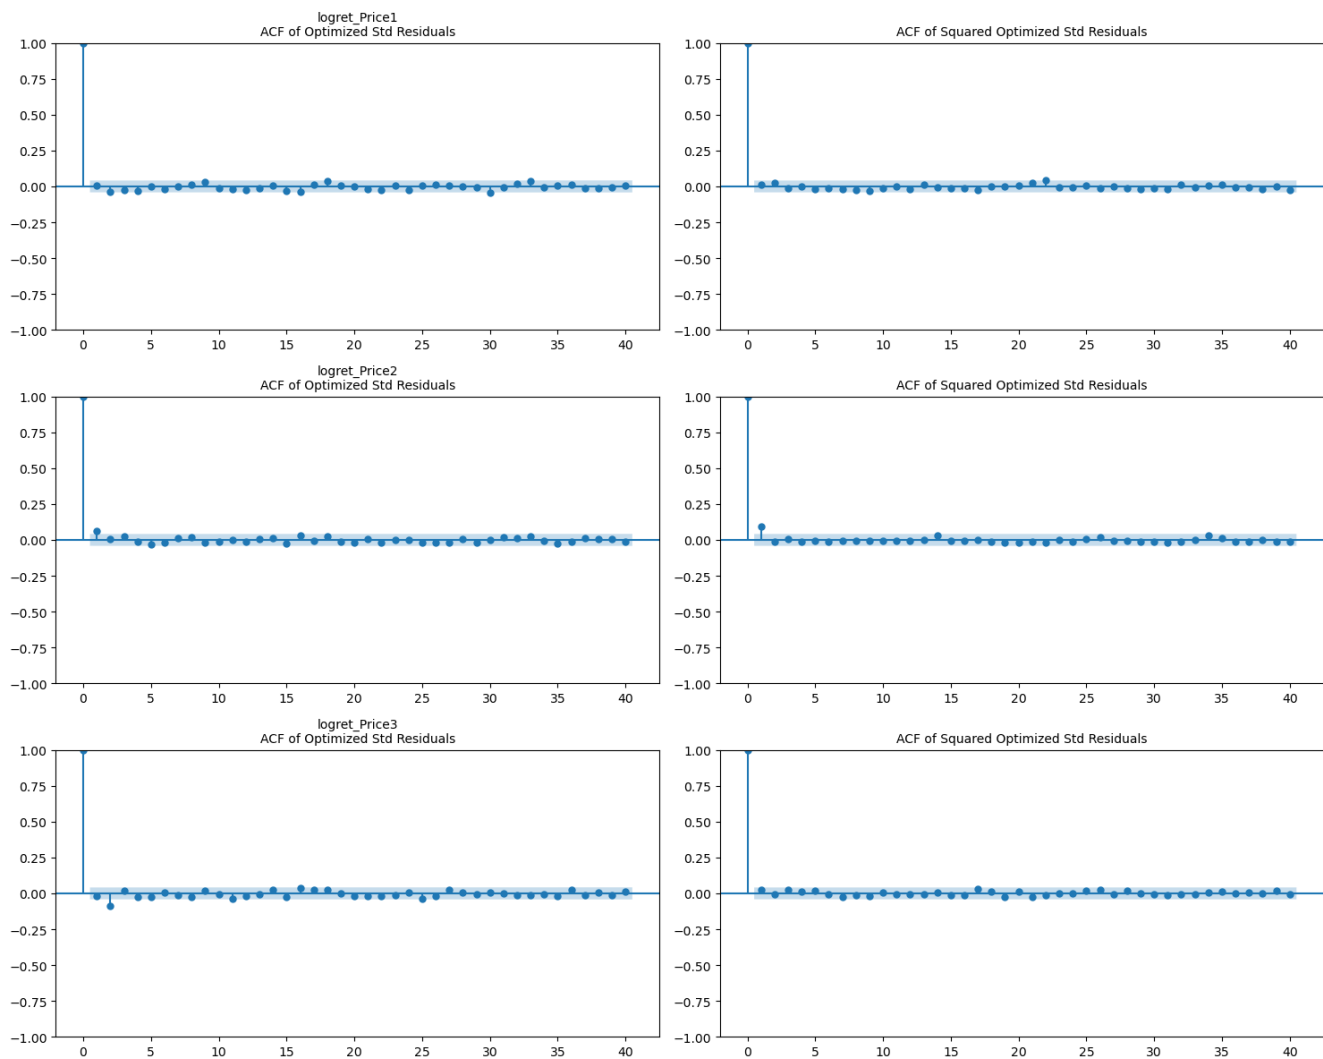

Figure 22: ACF of the Residuals in ARMA-GARCH models

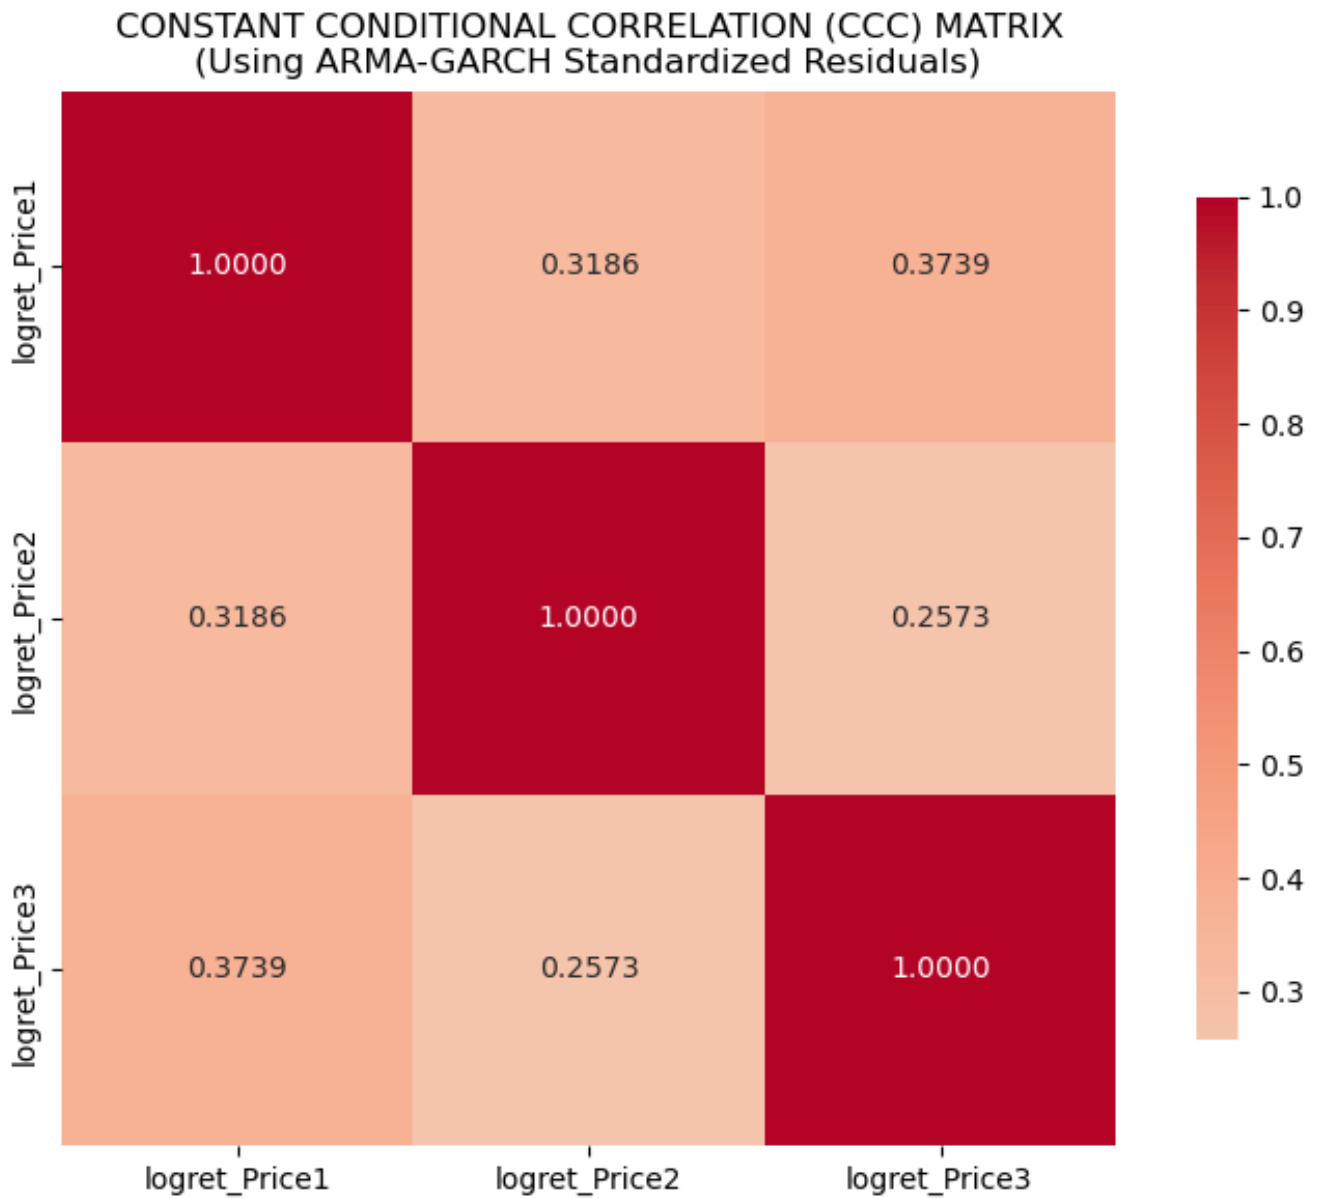

Figure 23: Constant Conditional Correlation Matrix

Table 13: DCC-GARCH Parameter Estimates

Parameter	Estimate	Statistical Meaning	Interpretation
$\zeta$	0.007145	News Impact	0.71% of correlation shocks persist to next period
$\xi$	0.989137	Persistence	98.91% of correlation structure carries forward
$\zeta + \xi$	0.996282	Stationarity	Ensures covariance stationarity of DCC process
Half-life	186 periods	-	Time for correlation shocks to decay by half

Table 14: Statistical Model Comparison: CCC vs DCC

Criterion	CCC Model	DCC Model	Statistical Interpretation
Log-Likelihood	-3196.46	-3176.45	Higher likelihood indicates better fit
AIC	6398.93	6356.91	Lower AIC supports DCC specification
BIC	6416.10	6368.35	Lower BIC confirms DCC superiority
Likelihood Ratio	-	40.0214	Significant improvement (p less than 0.000001)

Table 15: Correlation Dynamics: Statistical Properties

Asset Pair	CCC	DCC Mean	Std. Dev.	Range	Variation Coefficient	Half-life
Price1-Price2	0.3186	0.3145	0.0848	0.3661	0.2695	186
Price1-Price3	0.3739	0.3725	0.0659	0.3461	0.1770	186
Price2-Price3	0.2573	0.2609	0.0613	0.3211	0.2350	186

### B.3 VAR Model Analysis

Table 16: Descriptive Statistics and Distributional Properties

Variable	Mean	Std. Dev.	Min	Max	Skewness	Kurtosis
Oil Price	-0.0233	0.5731	-1.9831	1.6035	0.197	0.145
Inflation	-0.0095	0.6001	-1.6722	2.0177	0.422	0.481
GDP Growth	-0.0000	0.5330	-1.4505	1.7034	-0.158	-0.135

Table 17: Correlation Matrix

	Oil Price	Inflation	GDP Growth
<b>Oil Price</b>	1.000	0.643	-0.041
<b>Inflation</b>	0.643	1.000	-0.169
<b>GDP Growth</b>	-0.041	-0.169	1.000

Table 18: Stationarity Test Results and Modeling Decision

Variable	ADF p-value	KPSS p-value	Decision
Oil Price	0.0000	0.1000	Stationary
Inflation	0.0000	0.1000	Stationary
GDP Growth	0.0000	0.1000	Stationary

Table 19: Granger Causality Matrix

Predictors/Response	Oil Price	Inflation	GDP Growth
<b>Oil Price</b>	-	0.0001	0.1181
<b>Inflation</b>	0.0000	-	0.4206
<b>GDP Growth</b>	0.0160	0.0006	-

rows=Predictor; columns = Response

Table 20: VAR(1) Model Coefficient Estimates and Statistical Significance

	Oil Price	Inflation	GDP Growth
<b>Constant</b>	-0.0113	0.0032	0.0049
<b>L1.Oil Price</b>	0.4609**	0.3267**	0.0215
<b>L1.Inflation</b>	0.2195**	0.5507**	-0.1202
<b>L1.GDP Growth</b>	0.0879	-0.0621	0.5211**

Table 21: Residual Diagnostics and Model Adequacy Tests

Diagnostic Test	Results
Ljung-Box Test	All p-values $\geq 0.56$
ARCH Effects Test	Oil: 0.9785, Inflation: 0.7857, GDP: 0.4761 (No ARCH)
Information Criteria	AIC: -5.337, BIC: -5.214, Log-Likelihood: -602.696
Residual Correlation	Oil-Inflation: 0.370, Oil-GDP: 0.005, Inflation-GDP: -0.008

Table 22: Forecast Accuracy and Out-of-Sample Performance

Variable	RMSE	Interpretation
Oil Price	0.2972	Good forecasting accuracy predictive performance
Inflation	0.2734	
GDP Growth	0.7544	Uncertainty - typical for growth forecasts

12-month out-of-sample forecast evaluation

Table 23: Cointegration Analysis: Johansen Test Results

Test Statistic	Value
Trace Statistic Critical Value (95%)	29.796
Number of Cointegrating Relationships	3
Cointegration Rank	Full Rank
Strong evidence of long-run equilibrium relationships among all three variables	

Table 24: Comprehensive Model Validation Summary

Validation Check	Status and Interpretation
Stationarity	All variables strongly stationary
Residual Autocorrelation	No significant autocorrelation
ARCH Effects	No conditional heteroscedasticity
Cointegration	Strong evidence of long-run relationships
